Improving nonlinear and nonhydrostatic ocean lee wave drag

parameterizations

and Environmental Engineering, Stanford, California.

ABSTRACT

Ocean lee waves occur on length scales that are smaller than the grid scale of Global Circulation Models (GCMs). Therefore, such models must parameterize the drag associated with launching lee waves. This paper compares the lee wave drag predicted by existing parameterizations with the drag measured in high-resolution nonhydrostatic numerical simulations of a lee wave over periodic sinusoidal bathymetry. The simulations afford a time-varying glimpse at the nonlinear and nonhydrostatic oceanic lee wave spin-up process and identify a characteristic timescale to reach steady state. The maximum instantaneous lee wave drag observed during the spin-up period is found to be well predicted by linear lee wave theory for all hill heights. In steady state, the simulations demonstrate the applicability of parameterizing the drag based on applying linear theory to the lowest over-topping streamline of the flow (LOTS), as is currently employed in GCMs. However, because existing parameterizations are based only on the height of the LOTS, they implicitly assume hydrostatic flow. For hills tall enough to trap water in their valleys, the simulations identify a set of nonhydrostatic processes that can result in a reduction of the lee wave drag from that given by hydrostatic parameterizations. The simulations suggest implementing a time-dependent nonhydrostatic version of the LOTS-based parameterization of lee wave drag and demonstrate the remarkable applicability of linear lee wave theory to oceanic lee waves.

2

1. Introduction

In the ocean, because lee waves occur on length scales smaller than the resolution of global ocean circulation models (GCMs), the lee wave drag must be parameterized. Existing parameterizations are based on steady-state solutions for the flow above "linear-height" hills, wherein the height of the hill is much smaller than the wavelength of the wave (Bell 1975b; Gill 1982). Most common among the unresolved bathymetric features of the deep ocean are the abyssal hills which are statistically homogeneous on a regional scale and thus submit well to a spectral model (Goff and Jordan 1988). This allows for calculation of the lee-wave drag with the spectral linear theory of Bell (1975b,a). However, because a significant portion of the abyssal hills have nonlinear heights (Nikurashin et al. 2014), spectral linear theory is not formally valid in these regions.

At the bottom of the ocean, where the background horizontal velocity U and buoyancy frequency N are nearly constant with height, lee wave dynamics can be described in terms of the lee wave Froude number $J = Nh_0/U$ and the nonhydrostatic parameter $\epsilon = Uk/N$, where h_0 and k are the hill height and wavenumber (Mayer and Fringer 2017). Using the lee wave Froude number, J, nonlinear lee waves can be separated into two regimes: subcritical, $J = Nh_0/U < J_c$, and supercritical, $J = Nh_0/U \geq J_c$, where $J_c = O(1)$ is the critical Froude number. The supercritical regime is characterized by dramatic deviations of the form drag from the predictions of linear theory. Above isolated bathymetry, the flow on the downslope side of the isolated hill displays a standing hydraulic jump-like feature called a "downslope windstorm," with an associated pressure anomaly resulting in as much as an eight-fold amplification of the steady-state drag above the linear prediction (Peltier and Clark 1979; Pierrehumbert 1987). However, for supercritical lee waves above periodic bathymetry, such as the abyssal hills, the upslope of the next hill inhibits the formation of the downslope windstorm, and the flow instead displays a process called "blocking,"

3

wherein the lowest parcels of water become trapped in the valleys (e.g. Welch et al. 2001; Nikurashin and Ferrari 2010a; Winters 2016). In the presence of blocking, some water passes over the hills and generates lee wave energy. In steady state, this over-topping fluid travels along a streamline that is different from the bathymetry. The resulting wave is therefore identical to a subcritical lee wave generated by the lowest over-topping streamline, which we will refer to as the LOTS. High-resolution nonlinear numerical simulations of atmospheric lee waves demonstrate that the supercritical lee wave drag scales with the trough-to-crest height of the LOTS, which is observed to be $O(U/N)$ (Stein 1992; Welch et al. 2001; Eckermann et al. 2010). Thus atmospheric wave drag parameterizations posit that the wave drag over supercritical height hills is given by substituting an effective Froude number $J_{eff} \approx 1$ for J in linear theory (Palmer et al. 1986; Pierrehumbert 1987; Lott and Miller 1997; Garner 2005). We will refer to this approach as saturation theory.

As a package, the spectral model of the abyssal hills combines with saturation theory to permit computationally cheap calculations of the lee wave drag over arbitrary height, subgrid-scale abyssal hills in ocean models. This is the approach employed in recent studies of GCMs (Nikurashin and Ferrari 2011; Scott et al. 2011; Naveira Garabato et al. 2013; Melet et al. 2014; Trossman et al. 2013, 2015, 2016; Wright et al. 2014; Yang et al. 2018, 2019). These studies conclude that globally, lee wave drag constitutes between 0.2 to 0.75 TW of work on the ocean, meaning lee waves could be of principle importance for balancing the $O(1)$ TW of wind work at the ocean surface (Ferrari and Wunsch 2009). However, direct observations of lee waves in supercritical regions such as the Drake Passage (Cusack et al. 2017) and Kerguelen Plateau (Waterman et al. 2013) display dissipation rates one order of magnitude smaller than predicted by combining saturation theory with an energy-dissipation parameterization (St. Laurent et al. 2002). To account for this discrepancy, recent papers have implicated the interaction of geostrophic and tidal currents (Shakespeare 2020) and the absorption of wave energy aloft via conservation of wave action in vertically sheared flow

70 (Kunze and Lien 2019). In their introduction, Kunze and Lien (2019) offer a handful of additional

71 hypotheses, including measurement and instrument error, under sampling, wave-wave interaction,

72 a narrow radiating bandwidth, and, finally, that lee wave saturation is incompletely parameterized.

73   Saturation theory, as presented above, is based on lee waves of atmospheric scale, where the

74 forcing is hydrostatic. Assuming hydrostatic forcing implies that the wave drag is only a function

75 of hill height, or nondimensionally, of J, and not also a function of hill length (nondimensionally ϵ)

76 (Pierrehumbert 1987). However, in the $J - \epsilon$ regime appropriate to lee waves over abyssal hills in

77 the ocean, nonhydrostatic effects are important, even for subcritical height bathymetry (Mayer and

78 Fringer 2020). Nikurashin and Ferrari (2010a) and Nikurashin et al. (2014) are an exception to the

79 existing lee wave literature in that their simulations employ high-resolution nonhydrostatic models

80 and capture a $J - \epsilon$ regime appropriate for abyssal hill lee waves. However, both studies derive

81 their prediction for J_{eff} without varying the horizontal component of the generating bathymetry.

82 Thus, although their simulations incorporate nonhydrostatic processes, using their result for J_{eff}

83 to parameterize the lee wave drag above arbitrary bathymetry is still implicitly hydrostatic because

84 it assumes that the drag is independent of hill length.

85   Additionally, existing saturation based parameterizations assume both that the lee wave has

86 reached a steady state and that the momentum radiating through the wave is deposited within the

87 first wavelength above the bathymetry. However, for a linear lee wave in regions with negligible

88 rotational effects, the drag is an intrinsically unsteady feature that propagates vertically with the

89 lee wave front, such that the drag only acts on the bottom currents during the earliest period of

90 lee wave generation (Pedlosky 2003). This vertically propagating lee wave drag should also exist

91 in the supercritical regime because supercritical hills still launch subcritical lee waves. Although

92 rotation complicates this by permitting lee wave/inertial oscillation interaction (Nikurashin and

5

93 Ferrari 2010a), the assumption of steady-state lee waves depositing their momentum within the

94 first wavelength above the bathymetry is likely not justified everywhere in the ocean.

95 This paper offers a process study of an idealized lee wave to illuminate the consequence of

96 ignoring nonhydrostatic and unsteady effects when parameterizing oceanic lee wave drag. The

97 results are based on high-resolution, nonhydrostatic simulations of lee waves above sinusoidal hills

98 spanning the $J - \epsilon$ range of oceanic flow over abyssal hills. The paper is organized as follows: in

99 Section 2 we review the linear theory. In Section 3 we describe the numerical model and discuss

100 methods for measuring the lee wave drag. In Section 4 we analyze the temporal evolution of a

101 subset of subcritical and supercritical simulations. In Section 5 we evaluate the steady-state drag

102 and LOTS measured in all of the simulations. And in Section 6 we conclude with recommendations

103 for nonhydrostatic and time-dependent corrections to saturation theory.

2. Linear theory and parameter space

105 As in Mayer and Fringer (2017), we assume a non-rotating ocean with a free-slip bottom

106 boundary condition and an infinite depth. Although rotation is important at the scale of abyssal

107 hills ($O(1 - 10)$ km) in much of the ocean, where its primary contribution is to enforce a lower

108 bound on the radiating bandwidth of lee waves according to $f < Uk < N$, the following theory

109 and simulations are greatly simplified by omitting it. We discuss the ramifications of ignoring

110 rotation in the Conclusion. With the above assumptions, the lee wave is uniquely characterized

111 by $J = Nh_0/U$ and $\epsilon = Uk/N$. Mayer and Fringer (2017) demonstrate that $J = Nh_0/U$ is the lee

112 wave Froude number formed by the ratio of perturbation advection within the lee wave to the group

113 velocity of the lee wave. The second dimensionless number, $\epsilon = Uk/N$, can be cast as a ratio of

114 the wavelength of the lee wave in the direction of the wave-vector, $\lambda_{lee} = 2\pi U/N$, to the horizontal

115 wavelength of the bathymetry, $L_{hill} = 2\pi/k$. In terms of ϵ, the vertical wavenumber of the lee wave

6

116 is given by

$$m = \frac{N}{U}(1 - \epsilon^2)^{1/2}. \tag{1}$$

117 With increasing ϵ (increasing nonhydrostasy), the lee wave wavenumber vector points increasingly

118 downstream. When $\epsilon > 1$, the wavenumber of the hill is larger than the lee wave wavenumber,

119 implying an imaginary vertical wavenumber and thus a decaying, or evanescent, lee wave.

120   Abyssal hills are periodic and quasi-anisotropic in nature, with horizontal aspect ratios of between

121 1:3 and 1:8 (Goff and Arbic 2010, Fig. 1), such that they appear as ridge-like corrugations on the

122 ocean floor. As an idealization, we consider the simple sinusoidal bathymetry

$$h(x) = \frac{1}{2}h_0 \sin(kx). \tag{2}$$

123 The factor of $1/2$ is used so that h_0 is the trough to crest height of the hill. This convention follows

124 Lilly and Klemp (1979) and Welch et al. (2001), but differs from Nikurashin and Ferrari (2010a),

125 where the authors omit the factor of $1/2$. Hence the height scale in Nikurashin and Ferrari (2010a)

126 relates to h_0 as $h_{NF} = h_0/2$. Using Eq. (2), Mayer and Fringer (2020) show that the dimensionless

127 steady-state nonhydrostatic linear form drag per wavelength is given by

$$\frac{F_{lin}}{\rho_0 U^3 N^{-1}} = \begin{cases} \frac{\pi}{4}J^2\left(1 - \epsilon^2\right)^{1/2} & \epsilon < 1, \\ \\ 0 & \epsilon \geq 1. \end{cases} \tag{3}$$

128 Eq. (3) indicates that the nondimensional drag on the background current associated with generating

129 lee waves grows in proportion to J^2, but decreases with decreasing hill length (increasing ϵ) until

130 the evanescent boundary $L_{hill} = \lambda_{lee}$, beyond which the steady-state drag vanishes.

131   Eq. (3) affords a number of important limits and extrapolations. The hydrostatic limit of Eq. (3)

132 is given by setting $\epsilon = 0$,

$$\frac{F_{hs}}{\rho_0 U^3 N^{-1}} = \frac{\pi}{4}J^2, \tag{4}$$

7

133 and represents the largest magnitude drag that can result from a lee wave over a hill with crest to

134 trough height h_0. From this expression, a scale for the computed drag in what follows is given by

$$F_{sat} = \rho_0 U^3 N^{-1}. \tag{5}$$

135 Finally, the prediction for drag offered by saturation theory can also be stated using Eq. (3), as in

136 Yang et al. (2018),

$$F_{Yang} = F_{lin} L^2, \tag{6}$$

137 where

$$L = \begin{cases} 1, & J < J_c, \\ J_{eff}/J, & J \geq J_c, \end{cases} \tag{7}$$

138 $J_c = O(1)$ is an empirically determined critical Froude number above which the drag saturates,

139 and J_{eff} is the Froude number of the resulting effective bathymetry. It is generally assumed that

140 $J_{eff} = J_c$. As a canonical example, in their nonhydrostatic simulations of lee waves above $\epsilon = 0.31$

141 sinusoidal hills, Nikurashin and Ferrari (2010a) find that saturation occurs when $Nh_{NF}/U = 0.7$.

142 Recalling that $h_{NF} = h_0/2$, this implies a critical Froude number $J_{NF} = 1.4$.

143 All existing parameterizations assume a steady process in which the lee wave extracts momentum

144 continuously from the currents within one lee wave wavelength (≈ 500 m) of the bottom. However,

145 irrotational linear theory (e.g. Pedlosky 2003) suggests that the lee wave drag only acts on the

146 background current in the vicinity of the wave front, which propagates with vertical group velocity

$$C_z = \epsilon U (1 - \epsilon^2)^{1/2}. \tag{8}$$

147 This picture is complicated by rotation, where the more hydrostatic hills, for which $Uk \to f$, result

148 in an infinite vertical wavenumber, a vanishing vertical group velocity, and thus an evanescent

149 response (Klymak 2018; Kunze and Lien 2019). Nevertheless, the general observation that the lee

8

150 wave drag is felt only within the vicinity of the vertically propagating wave front remains valid.

151 Presumably, the same temporal effect is present in nonlinear lee waves because, as posited by

152 saturation theory, there is still a subcritical lee wave generated by the LOTS, and thus still a wave

153 front where the lee wave drag acts.

154 The theory presented in this section suggests that lee waves above nonlinear and nonhydrostatic

155 bathymetry should exhibit nonlinear, nonhydrostatic, and time-dependent behavior. However, at

156 present, saturation theory offers an hydrostatic and steady-state parameterization for the lee wave

157 drag. To quantify significance of omitting nonhydrostatic and time-dependent effects, we turn to

158 numerical simulations of the idealized oceanic lee wave.

3. Numerical model
159

a. Model set-up
160

161 Our simulations employ the nonhydrostatic Navier Stokes solver SUNTANS (Fringer et al. 2006).

162 The set-up, sketched in Fig. 1, is identical to that in Mayer and Fringer (2020), with a uniform

163 buoyancy frequency $N = 0.002\,\mathrm{s}^{-1}$ and constant volume-averaged horizontal velocity $U = 0.2\,\mathrm{m\,s}^{-1}$

164 such that the lee wave wavelength is $\lambda_{lee} = 2\pi U/N = 628$ m. Because we are primarily interested

165 in lee waves in the deep ocean, where the free surface plays a negligible role, the domain in all

166 simulations is 7 km deep and employs a sponge layer throughout the upper 5 km. The vertical

167 grid-spacing is a constant $\Delta z = 5$ m beneath the sponge layer (the bottom 2 km of the domain),

168 and stretches linearly within the sponge layer until $\Delta z = 300$ m at the surface. This is identical

169 to the vertical grid used in Nikurashin and Ferrari (2010a). The simulations begin at rest and are

170 spun-up with a forcing scheme that ensures a constant volume-averaged streamwise velocity U

171 (Nelson and Fringer 2017). As described in Mayer and Fringer (2020), the kinematic viscosity is a

9

172 constant $\nu = 0.01$ m^2 s^{-1}, and no explicit turbulence model is employed. Shakespeare and Hogg

173 (2017) suggest that this value for ν is small enough to produce an effectively inviscid linear lee

174 wave simulation (see their Fig. 3.c) . Tests of our model set-up with smaller viscosity (not shown)

175 display little dependence on the Reynolds number, defined by $Re = U/(\nu k)$.

176   Whereas in Mayer and Fringer (2020), we only varied the length of the sinusoidal hill (Eq. 2),

177 in this paper we now vary both the height and length over the set $h_0 = [2$ m to 200 m$]$ and

178 $L_{hill} = [4$ km to 800 m$]$. This samples the parameter space $J = [0.02$ to $2]$ and $\epsilon = [0.16$ to

179 $0.8]$, which is characteristic of lee waves over abyssal hills (Goff and Arbic 2010; Nikurashin

180 and Ferrari 2011). Anticipating that nonlinear-height lee waves might take longer to reach steady

181 state, each simulation in this paper is run for 20 excitation periods, $T_{ex} = L_{hill}/U$. Additionally,

182 all simulations are nonhydrostatic with a constant horizontal resolution of $\Delta x = 10$ m. This avoids

183 both the unphysical over-prediction of the wave drag caused by using a hydrostatic model with

184 nonhydrostatic-length bathymetry as well as the under-prediction in wave drag caused by poorly

185 resolving the bathymetry (Mayer and Fringer 2020).

186 *b. Computing the lee wave drag*

187   This study employs two methods to compute the simulated lee wave drag. The first uses the

188 simulated pressure p at the bottom ($z = h(x)$) and the analytical bathymetry $h(x)$ to directly compute

189 the form drag as

$$F_{form} = \int_0^{Lhill} p(x, z = h(x)) \frac{\partial h}{\partial x} \, dx. \tag{9}$$

190 A second measurement of the lee wave drag is provided by integrating the vertical momentum flux

191 through an horizontal plane above the bathymetry. Unless otherwise noted in what follows, we

10

192 choose this plane to be a height $z_t = 15$ m above the crest of the hill, and define

$$F_{flux} = \int_0^{Lhill} \rho_0 u(x, z_t) w(x, z_t) \, dx. \tag{10}$$

193 For a steady inviscid lee wave over a linear hill, $F_{form} = -F_{flux}$ analytically. Viscous effects are

194 negligible in the ocean, and still small for $z_t \ll \lambda_{lee}$ even with the relatively large viscosity in our

195 model (Shakespeare and Hogg 2017).

196 The relationship between the form drag and momentum flux is demonstrated by the governing

197 area-integrated horizontal momentum equation, which is given by

$$\frac{dM}{dt} = -F_{flux} - F_{form}, \tag{11}$$

198 where

$$M = \rho_0 \int_A u \, dA \tag{12}$$

199 is the area-integrated momentum per unit span. In equilibrium $dM/dt = 0$, implying $F_{flux} =$

200 $-F_{form}$. However, the time-integrated momentum equation produces nonzero M when unsteadiness

201 and nonlinearities lead to imbalances between F_{flux} and $-F_{form}$, as discussed in what follows.

4. Unsteady behavior of lee waves

a. Subcritical, weakly-nonlinear case ($J = O(0.1)$)

204 Before interrogating the supercritical simulations, in this section we consider a simulation over a

205 weakly nonlinear but still subcritical height hill. For this purpose, the 4 km long and 60 m tall hill

206 ($\epsilon = 0.16$, $J = 0.6$) is a good example. Snapshots of the nondimensional vorticity ($\omega^* = \omega/(JN)$)

207 and streamlines every half T_{ex} are shown in Fig. 2. Note that the wave front travels upward with

208 group velocity, $C_z = \epsilon U (1 - \epsilon^2)^{1/2}$ (Eq. 8). For this hydrostatic hill, the nonhydrostatic effect is

209 negligible since $(1 - \epsilon^2)^{1/2} = 0.987$. Hence, $C_z \approx \epsilon U = \lambda_{lee}/T_{ex}$ such that after one excitation

11

₂₁₀ period, the wave front has traveled approximately one wavelength into the water column. After

₂₁₁ two excitation periods, the wave is fully established within the domain shown, and little changes

₂₁₂ over the following half T_{ex}.

₂₁₃   The lowest parcel of water in this weakly nonlinear simulation struggles to flow over the hill

₂₁₄ during spin up, such that at $t = T_{ex}/2$, in Fig. 2, there is a small jump in vorticity halfway up the

₂₁₅ hill. By the next snapshot, at $t = T_{ex}$, this bottom water has traveled over the hill and no longer

₂₁₆ presents an obstacle. Nevertheless, the sharp gradients in vorticity lead to mixing and a reduction

₂₁₇ of the buoyancy frequency near the bottom. Fig. 3 shows the horizontally-averaged instantaneous

₂₁₈ buoyancy frequency $\langle N \rangle$ for this simulation at times corresponding to those in Fig. 2, as well as

₂₁₉ later times, where we define $\langle N \rangle$ as

$$\langle N \rangle = \frac{1}{L_{hill}} \int_0^{L_{hill}} \left(-\frac{g}{\rho_0} \frac{\partial \rho}{\partial z} \right)^{1/2} dx. \tag{13}$$

₂₂₀ In Fig. 3, the decay of the buoyancy frequency near the bottom is significant. By $t = T_{ex}$, $\langle N \rangle$

₂₂₁ at the bottom of the valley is roughly 25% smaller than the background N, and it continues to

₂₂₂ decay throughout the simulation. However, the decay remains confined to a region $\delta = U/N$ above

₂₂₃ the hill (indicated by the dashed horizontal line in Fig. 3). A similar bottom-confined decay of

₂₂₄ buoyancy frequency was observed in the lee wave simulations of Klymak (2018), where it was

₂₂₅ likewise attributed to the spin up of the system from rest. There is reason to believe that the

₂₂₆ phenomenon exists in nature. For example, observations in locations ripe for lee waves such as

₂₂₇ the Antarctic Circumpolar Current north of the Kerguelen plateau (Waterman et al. 2013) and the

₂₂₈ Hoyt Hills region of the Gulf current (Zheng et al. 2012) indicate bottom layers with thickness

₂₂₉ approximately equal to U/N. Note that this decay of near-bottom buoyancy frequency is only an

₂₃₀ issue for periodic bathymetry. For an isolated hill, the mixing during spin up would momentarily

₂₃₁ reduce the stratification above the hill, but not that of upstream fluid that flows over the hill at later

12

times. Hence the steady-state dynamics of a lee wave above a given hill are only sensitive to the local decay of buoyancy frequency during spin up when there are other hills upstream to do the initial mixing.

To approximate the effect of a decayed bottom buoyancy frequency on the lee wave above periodic bathymetry, we define an adjusted bottom-layer buoyancy frequency by averaging $\langle N \rangle$ from $z = 0$ to $z = h_0 + U/N$ with

$$N_{adj} = \frac{1}{h_0 + U/N} \int_0^{h_0 + U/N} \langle N \rangle \, dz, \tag{14}$$

where $z = 0$ is taken at the bottom of the valley. Inspection of Eq. (4) shows that the hydrostatic wave drag is proportional to the buoyancy frequency, $F_{lin} \propto N$. Thus a reduction in the buoyancy frequency over a layer δ above the bathymetry should result in smaller form drag, which we can approximate by substitution of N_{adj} for N in Eq. (3), giving

$$F_{adj} = \frac{N_{adj}}{N} F_{lin}. \tag{15}$$

Note that this expression ignores the nonhydrostatic effect of N_{adj} on the vertical wavenumber (Eq. 1). We found that incorporating an adjusted vertical wavenumber m_{adj} produced unphysical predictions, especially above the more nonhydrostatic hills. Above these narrow hills, N_{adj} implies imaginary m_{adj} and evanescent waves (since $Uk > N_{adj}$), even though the disturbance generates a propagating wave in the region above the decayed buoyancy. In Fig. 4, we compare F_{adj} to the computed form drag (Eq. 9) and vertical momentum flux (Eq. 10) in the subcritical simulation shown in Fig. 2. The adjusted linear theory accurately predicts the general evolution of the computed drag over the course of the simulation. As demonstrated in the following section, the adjusted linear theory works equally well during steady state (see Fig. 10 and 11). Hence, for subcritical simulations, we should expect a smaller drag than predicted by linear theory, F_{lin} (Eq. 3), due to the decay of buoyancy in the lowest layers. Additionally, in regions where rotation is important,

13

253   the decay in buoyancy frequency narrows the $N - f$ frequency band for propagating lee waves. For

254   a field of abyssal hills with varying wavenumber, the decay of near-bottom buoyancy frequency

255   thus has the consequence of further reducing the total lee wave drag (Kunze and Lien 2019).

256   The subcritical example also affords an opportunity to study the progression of the wave front as

257   it propagates away from the hill. In Fig. 5, we display F_{flux} (Eq. 10) as a function of height above

258   the bottom at different points in time. Note that the wave front has a vertical extent of roughly

259   one lee wave wavelength, $\lambda_{front} \approx \lambda_{lee}$, and propagates vertically at a rate of approximately one

260   λ_{lee} for each T_{ex}, as predicted by hydrostatic linear theory. Also note that after the wave front has

261   reached the sponge layer, the momentum flux is nearly constant with height, with a slight decay

262   with distance from the bottom as predicted by viscous effects (Shakespeare and Hogg 2017). The

263   non-divergent momentum flux confirms the hypothesis of Pedlosky (2003) that in the subcritical

264   regime after spin up, the lee wave drag is not felt by the lowest water, where the momentum flux

265   is non-divergent, but aloft in the vicinity of the propagating wave front. From the perspective of a

266   GCM, this supports the notion that lee wave drag parameterizations could account for unsteadiness

267   by appropriately positioning the drag in the vertical rather than always assigning it to the bottom

268   layer.

269   *b. Supercritical cases ($J > 1$)*

270   In this section we report on the temporal evolution of three supercritical simulations with hills of

271   constant height, $h_0 = 160$ m ($J = 1.6$), but different length, $L_{hill} = [4, 2, 1]$ km ($\epsilon = [0.16, 0.32, 0.63]$).

272   This subset illuminates both similarities across supercritical lee waves with different values of ϵ and

273   important quantitative discrepancies in the form drag, especially for the narrowest hill ($\epsilon = 0.63$).

274   The temporal evolution of vorticity and streamlines over the first 2.5 T_{ex} for the three supercritical

275   hills (Fig. 6) demonstrates a remarkable qualitative similarity between lee waves over supercritical

14

276 hills of dramatically different widths. In all three simulations, the lowest parcels of water become

277 blocked and induce separation on the downslope face within the first half excitation period. Within

278 another excitation period, the shear between the over-topping flow and the blocked layer evolves

279 into a train of vortices that populate the valley. Thereafter, these qualitative features of the blocked

280 layer change little. Thus, the excitation period T_{ex} again offers a reasonable time scale for the lee

281 wave to reach steady state.

282 More quantitatively, Fig. 7 shows the form drag, F_{form} (Eq. 9), and the vertical momentum

283 flux through a horizontal plane 15 m above the hill, F_{flux} (Eq. 10), for $0 \leq t \leq 6\,T_{ex}$. All

284 three simulations exhibit large discrepancies between the two measures of drag during $t < T_{ex}$,

285 indicating significant momentum deposition during this period. After the first T_{ex}, however, the

286 simulations display nearly balanced form drags and momentum fluxes, implying that, just as in the

287 subcritical example, the momentum within the control volume is only altered during the first T_{ex}

288 of the simulation (Eq.11). For the two longer hills ($\epsilon = [0.16, 0.31]$), F_{form} and F_{flux} stabilize at

289 around $0.4\,F_{sat}$ (Eq. 5), in accordance with saturation theory. However, the narrowest hill ($\epsilon = 0.63$)

290 stabilizes at a much smaller magnitude. Above such a narrow hill, the blocked layer quickly fills

291 enough of the valley to render the entire over-topping streamline evanescent, a point to which we

292 return below.

293 The large discrepancies between the maximum F_{form} and F_{flux} during the first T_{ex} is unique

294 to the supercritical simulations and results in a significant change to the momentum of the fluid

295 within the control volume (Eq.12). Comparison with the flow for $t < 2\,T_{ex}$ displayed in the top

296 panels of Fig. 6 encourages the interpretation that the local momentum deposition serves to arrest

297 the valley water and establish the blocked layer, as expected for supercritical periodic bathymetry

298 (Welch et al. 2001). We can estimate the horizontal momentum change M'_b required to block the

299 valley water as a product of the volume V_b contained within the blocked layer and the background

15

velocity U, viz.

$$M_b' = \rho_0 V_b U. \tag{16}$$

We compute this value at the time T_b, which we define as the first instance that $F_{flux} = F_{form}$, and compare it to the change in momentum within the control volume during the time period, computed by integrating Eq. (12) from $t = 0$ to $t = T_b$. For these three hills ($\epsilon = [0.63, 0.32, 0.16]$), the comparison gives the ratios $M_b'/M' = [1.23, 0.92, 0.92]$. This close equivalence confirms that the imbalance in the form drag and the vertical momentum flux during the spin up of these supercritical lee waves indeed serves to establish the blocked layer.

The observation that for the two longer hills ($\epsilon = [0.16, 0.31]$), the maximum value of the form drag is well approximated by the prediction of linear theory, F_{lin} (Eq. 3), while the momentum flux instead peaks around the saturation value $F_{sat} = \rho_0 U^3 N^{-1}$ (Eq. 5), as predicted by saturation theory, suggests that a scale for the local momentum deposition is given by $M_b' \sim T_{ex}(F_{lin} - F_{sat})$. To test this observation, Fig. 8 displays contour plots of the maximum computed vertical momentum flux and form drag for all simulations in this study, as well as the linear prediction (Eq. 3). The close correspondence between the maximum computed form drag and the prediction from linear theory is remarkably robust across most of the $J - \epsilon$ regime spanned by the simulations, especially for $\epsilon \leq 0.5$. Likewise, the vertical momentum flux displays ubiquitous saturation of $O(F_{sat})$. Conceptually, this supports the general conclusion that during the first excitation period the form drag reaches the linear value, but the background conditions imposed by U and N restrict the momentum flux to the saturation value F_{sat}. The extra form drag thus acts to decelerate the valley water and establish a blocked layer. However, because the momentum sink is restricted to the first excitation period of lee wave generation, it is dramatically different from the parameterizations for the non-propagating drag found in Pierrehumbert (1987) and Garner (2005), for which the local momentum sink is assumed to persist into steady state.

16

323   Finally, in Fig. 9 we show the evolution of the LOTS for the simulations in Fig. 6 for time

324 $t \leq 16\,T_{ex}$. We note that the separated portion of the LOTS in each simulation displays persistent

325 undulations with length scales of approximately λ_{lee}. Furthermore, the LOTS evolves very slowly

326 for $t > 6\,T_{ex}$, indicating that the simulations indeed approach a quasi-steady state. Thus, in what

327 follows, quantities with the overbar (e.g. $\overline{u}$) are time-averaged during $6\,T_{ex} \leq t < 12\,T_{ex}$.

328   The time-variable LOTS in Fig. 9 can be used to explain the dramatic reduction in drag observed

329 in the very nonhydrostatic $\epsilon = 0.63$ hill after the establishment of the blocked layer.   In all

330 supercritical simulations, once the blocked layer is formed, the LOTS has two different sections,

331 one that is defined by the unblocked portion of the bathymetry, and another that is separated from

332 the bathymetry. For the simulation above the narrow $\epsilon = 0.63$ hill, the separated section of the

333 LOTS comprises more than half of the total LOTS. As discussed in more detail in the next section,

334 the separated portion of the LOTS is evanescent and does not generate lee waves. However, for this

335 narrow hill, the hill length is less than two lee wave wavelengths, as indicated by $\epsilon = \lambda_{lee}/L_{hill} > 0.5$.

336 Therefore the unseparated portion of the LOTS, which comprises less than half of the total LOTS,

337 is also evanescent to the flow, and thus exerts no drag after the establishment of the blocked layer.

338 This process, which we will term "evanescent masking," has dramatic effects on the steady-state

339 drag for all hills in which the unseparated portion of the LOTS is evanescent, as discussed in the

340 next section.

341 **5. Nonlinear, nonhydrostatic effects on time-averaged drag**

342   In this section, we analyze the steady-state lee wave drag in our simulations $\overline{F}_{SUN}$, obtained by

343 averaging F_{flux} (Eq. 10) over the period $6\,T_{ex} \leq t < 12\,T_{ex}$

$$\overline{F}_{SUN} = \frac{1}{6T_{ex}} \int_{6\,T_{ex}}^{12\,T_{ex}} F_{flux}\, dt, \tag{17}$$

17

₃₄₄ and compare the results with linear and saturation theory. Unless otherwise noted, we use the

₃₄₅ vertical momentum flux F_{flux} computed just above the hill (Eq. 10) rather than the direct com-

₃₄₆ putation of the form drag F_{form} (Eq. 9). The time-averaged drag as a function of J is shown in

₃₄₇ Fig. 10. In the top panel, the drag is nondimensionalized by $F_{sat} = \rho_0 U^3 N^{-1}$ (Eq. 5). This makes

₃₄₈ apparent that the drag grows with J up to a maximum of roughly $0.5 F_{sat}$ when $J = 1$. We identify

₃₄₉ blocking as occurring when the maximum vertical excursion of the time-averaged LOTS is less

₃₅₀ than 95% of the hill height. With this definition, blocking begins at $J = 1$ for the narrowest hills,

₃₅₁ and is present in all simulations for which $J > 1$, confirming the critical Froude number $J_c = 1$.

₃₅₂ In the middle panel of Fig. 10, the drags are instead nondimensionalized by the predictions from

₃₅₃ linear theory F_{lin} (Eq. 3). The effect of blocking in the supercritical simulations is again apparent.

₃₅₄ However, with this scaling it is evident that the time-averaged drag is smaller than linear theory

₃₅₅ predicts, even for $J < J_c$. The discrepancy in the unblocked cases is a consequence of the reduction

₃₅₆ of the stratification near the bottom during lee wave spin up, as discussed in Section 4.a. Indeed,

₃₅₇ normalizing the drag by F_{adj} (Eq. 15) instead of F_{lin}, as in the bottom panel of Fig. 10, removes

₃₅₈ this trend. It also introduces a new source of noise for the most nonhydrostatic hills, possibly due

₃₅₉ to the effect of the reduced buoyancy frequency on the vertical wavenumber, which we neglect in

₃₆₀ computing F_{adj}. Together, the three panels demonstrate the separation of the lee wave into three

₃₆₁ regimes based on hill height: the linear limit $J \ll 1$, where F_{lin} (Eq. 3) is accurate, the subcritical

₃₆₂ regime $J = O(0.1)$, where weak nonlinearities during spin up result in a decay of buoyancy near

₃₆₃ the bottom and the drag is better predicted by the buoyancy adjusted linear theory F_{adj} (Eq. 15),

₃₆₄ and the supercritical regime $J \geq J_c$, in which the lowest parcels of water are trapped in the valleys

₃₆₅ and the drag is limited by the radiative capacity of the fluid, $F_{sat} = \rho_0 U^3 N^{-1}$ (Eq. 5).

₃₆₆ To demonstrate the dependence of drag on the hill length, Fig. 11 displays the time-averaged

₃₆₇ drag as a function of ϵ. In general, there is a monotonic decrease in the drag with increasing ϵ,

18

368 as predicted by linear theory (Eq. 3). At moderate values of $\epsilon = [0.57, 0.48, 0.42, 0.35]$, however,

369 the critical $J = 1$ and supercritical $J = 1.2$ height hills demonstrate interesting non-monotonic

370 behavior (highlighted by squares in Fig. 11). When $J = 1$, there is a maximum drag at $\epsilon = 0.48$, in

371 contradiction to linear theory. This non-monotonic behavior can be explained as a consequence of

372 harmonic resonance between the excitation frequency Uk and the responding buoyancy frequency

373 N. When $\epsilon = 0.5$, $N = 2Uk$, implying that the buoyancy frequency is a harmonic of the excitation

374 frequency, amplifying the nonlinear response. On the other hand, when $\epsilon = 1/3$ or $2/3$, $N = 3Uk$

375 and $3/2Uk$, implying a dissonant buoyancy frequency and muted response.

376   In Fig. 12 we show the correlation between the average computed drag and the drag predicted by

377 buoyancy adjusted linear theory F_{adj} (Eq. 15). We use F_{adj} rather than F_{lin} to remove the effect of

378 the reduced buoyancy frequency near the bottom on the predicted drag. From Fig. 12, it is clear

379 that using linear theory based on the length and height scales of the bathymetry is valid in the

380 linear and weakly nonlinear regimes, but fails as predicted by saturation theory when $J = O(1)$.

381 Fig. 12 also suggests that the more nonhydrostatic runs (smaller circles) are more strongly affected

382 by saturation.

383   As a measure of the strength of the correlation between simulations and parameterizations or

384 theory, we use the coefficient of determination, defined as

$$R^2 = 1 - \frac{SS_{res}}{SS_{tot}}, \tag{18}$$

385 where

$$SS_{tot} = \sum (y_i - \overline{y})^2 \tag{19}$$

386 is the sum of squared errors between the simulated values y_i and their mean $\overline{y}$, and

$$SS_{res} = \sum (y_i - f_i)^2 \tag{20}$$

19

387 is the sum of squared differences between the simulated values y_i and the parameterized values

388 f_i. A parameterization that perfectly predicts the simulated value will give $R^2 = 1$, while a

389 negative value of R^2 indicates that the observed values are better predicted by their mean than

390 by the parameterization. The coefficients of determination for all steady-state parameterizations

391 considered in this section are shown in Table 1. For linear theory using the adjusted buoyancy

392 frequency (Fig. 12), the coefficient of determination is $R^2 = -53.1$. The poor performance results

393 from using the bathymetric height to scale the drag in supercritical lee waves.

394   Fig. 13 shows the time-averaged LOTS for the simulations in Fig. 9. As posited by saturation

395 theory, the LOTS is the effective bathymetry that generates lee waves, which can be used to compute

396 the effective bathymetric power spectrum and thus predict the drag with the Fourier synthesis of F_{lin}

397 (Eq. 3), as in Bell (1975b). Because this method employs all of the horizontal information in the

398 LOTS, this operation represents a fully nonhydrostatic form of saturation theory. We perform this

399 analysis on each run that exhibits blocking and plot the correlation between the average computed

400 drag $\overline{F}_{SUN}$ (Eq. 17) and the drag predicted by F_{Bell} in the upper-left panel of Fig. 15. With

401 $R^2 = 0.901$, this combination of spectral linear theory with the LOTS is significantly better than

402 the linear theory that uses the bathymetric height and length, F_{adj}, for which $R^2 = -53.1$ (Fig. 12).

403 This demonstrates the strength of viewing the average LOTS as the effective wave-generating

404 bathymetry.

405   In practice, the power spectrum of the LOTS above abyssal hills is not known a priori. Indeed,

406 the usefulness of hydrostatic saturation theory is its prediction that, for supercritical bathymetry,

407 there exists some average effective hill height of $O(U/N)$ such that the effective wave generating

408 Froude number is $J_{eff} = O(1)$. To this end, we compute the average effective heights of each

409 LOTS, h_{eff}, as indicated in Fig. 14, and define an effective Froude number, $J_{eff} = Nh_{eff}/U$ to

20

410 form a simple prediction of the drag based on hydrostatic saturation theory

$$F_{eff} = \left(\frac{J_{eff}}{J}\right)^2 F_{adj}. \tag{21}$$

411 We perform this analysis on each run that exhibits blocking and compare the computed drag to the

412 drag predicted by F_{eff} in the upper-right panel of Fig. 15. Although using hydrostatic saturation

413 theory to compute F_{eff} gives a better prediction than linear theory (which has $R^2 = -53.1$; see

414 Table 1), with $R^2 = -0.331$, F_{eff} is still less predictive than the mean of the observations. It also

415 uniformly over predicts the lee wave drag.

416 The discrepancy between the performance of spectral saturation theory F_{Bell} and hydrostatic

417 saturation theory F_{eff} suggest that there is a characteristic component of the supercritical LOTS

418 that the latter neglects. We hypothesize that one important feature of the LOTS are the undulations

419 downstream of the separation points with wavelengths roughly equal to λ_{lee}. If these undulations are

420 treated as independent periodic bathymetry, they represent hills with $\epsilon \approx 1$ and are thus evanescent

421 and should not contribute to the drag. The total effective height of the LOTS can therefore be

422 partitioned into a propagating h_{prop} and a non-propagating $h_{non-prop}$ component, as illustrated in

423 Fig. 14. Note that we define $h_{non-prop}$ as the maximum height of the undulations above the blocked

424 layer rather than as the height of the jump-like feature at beginning of the blocked layer because

425 only the former of these features can be treated as independent periodic bathymetry. In this sense,

426 the separation of h_{eff} into h_{prop} and $h_{non-prop}$ represents an approximation of the power spectrum

427 of the LOTS by two primary components. Only the propagating component contributes to the

428 drag, suggesting that

$$F_{prop} = \left(\frac{J_{prop}}{J}\right)^2 F_{adj}, \tag{22}$$

429 where

$$J_{prop} = \frac{N}{U}\left(h_{eff} - h_{non-prop}\right). \tag{23}$$

21

430 The lower-left panel of Fig. 15 compares the computed drag to F_{prop}. It performs much better

431 than hydrostatic saturation theory with $R^2 = 0.718$, indicating that the evanescent undulations are

432 indeed dynamically relevant. However, F_{prop} is not as skilled as spectral saturation theory, and still

433 tends to overestimate the drag.

434 The signal of an evanescent lee wave decays with height above the ocean floor at a rate determined

435 by the vertical wavenumber (Eq. 1). Hence, a streamline sufficiently far from the bathymetry should

436 contain contributions from only the propagating component of the lee wave. This observation

437 leads to a final parameterization for the effective bathymetry, with an effective height h_{aloft} based

438 on the maximum vertical displacement of a streamline originating at $z = h_0 + \lambda_{lee}/2$ above the

439 crest of the hill (red-dotted lines in Fig. 13). The height h_{aloft} implies a new Froude number,

440 $J_{aloft} = N h_{aloft}/U$, and a new parameterization for the drag

$$F_{aloft} = \left(\frac{J_{aloft}}{J} \right)^2 F_{lin}. \tag{24}$$

441 As shown in Fig. 15, this drag prediction agrees remarkably well with the computed drag, with a

442 coefficient of determination of $R^2 = 0.956$. Similarly excellent performance (not shown) results

443 from selecting a streamline twice as far from the bottom. This parameterization has the added

444 advantage that it is insensitive to the decay of buoyancy near the bottom, since the streamline upon

445 which J_{aloft} is based is at a height above the observed decay. Furthermore, parameterizing the

446 drag with the aloft streamline does not require the spectrum of the streamline, as in the calculation

447 of F_{Bell}, only its maximum vertical excursion, h_{aloft}. The combination of simplicity and accuracy

448 in this parameterization suggests that a good estimate of the lee wave drag in the ocean may be

449 obtained simply by measuring the vertical excursion of a streamline at a height $z_{aloft} = \pi U/N$

450 above the bathymetry.

451 Upon averaging across all of the simulations that display blocking (indicated by a tilde), we

452 observe an average effective Froude number of $\tilde{J}_{eff} = 0.7 \pm 0.07$, an average propagating Froude

453 number of $\tilde{J}_{prop} = 0.5 \pm 0.06$, and an average aloft Froude number of $\tilde{J}_{aloft} = 0.4 \pm 0.09$. Unlike

454 most versions of saturation theory, in which $J_{eff} = J_c$, here all values for the effective Froude

455 number are smaller than the observed critical Froude number $J_c = 1$, indicating that a supercritical

456 lee wave has a smaller drag than a critical lee wave. Our values of $\tilde{J}_{eff}$, $\tilde{J}_{prop}$, and $\tilde{J}_{aloft}$ are

457 also significantly smaller than the the effective Froude number of Nikurashin and Ferrari (2010a),

458 J_{NF}=1.4 (this accounts for their definition of hill height, which is half of ours, i.e. $h_0 = 2\, h_{NF2010}$).

459 Thus, the nonhydrostatic corrections to simple saturation theory embodied by F_{prop} and F_{aloft}

460 suggest that the lee wave drag over supercritical abyssal hills could be 50% smaller than currently

461 thought. Furthermore, since $J_{aloft} < J_c/2$, these simulations suggest the most intense abyssal lee

462 waves occur instead over critical and nearly-critical abyssal hills, before the onset of blocking.

463 To summarize this section, Fig. 16 shows contour plots in $J - \epsilon$ space of the two measures

464 of time-averaged drag ($\overline{F}_{flux}$ and $\overline{F}_{form}$) and the four supercritical parameterizations for drag

465 discussed in this section (F_{eff}, F_{Bell}, F_{prop}, and F_{aloft}). Comparison of $\overline{F}_{flux}$ and $\overline{F}_{form}$ show

466 them to be identical ($R^2 = 0.97$), indicating that just as in the linear regime of Pedlosky (2003),

467 during the majority of the supercritical lee wave event over periodic bathymetry, the form drag and

468 the vertical momentum flux are in balance, and there is no change in momentum near the ocean

469 floor.

470 Fig. 16 also highlights a curious ϵ-dependent feature that is not predicted by hydrostatic saturation

471 theory, namely the precipitous decline in simulated drag when $J > 1$ and $\epsilon > 0.5$. We hypothesize

472 that this drop off is due to evanescent masking, wherein the blocked layer grows horizontally to

473 the point in which the attached portion of the LOTS becomes evanescent in length. Defining the

474 horizontal length of this unseparated portion as L_{launch} (see Fig. 14), we thus expect evanescent

23

475 masking when

$$L_{launch} < \lambda_{lee}. \tag{25}$$

476 The boundary predicted upon measuring L_{launch} in every simulation is sketched in the top left

477 panel of Fig. 16, and aligns remarkable well with the observed drop-off in drag. Evanescent

478 masking thus represents a second nonhydrostatic process present in oceanic lee waves above

479 periodic bathymetry which is also absent from current implementations of saturation theory. Like

480 the evanescent undulations over the blocked layer, evanescent masking has the effect of reducing

481 the lee wave drag above supercritical hills below that predicted by saturation theory. Indeed, for

482 the most supercritical simulations in this study, evanescent masking renders even the hydrostatic

483 hills practically evanescent.

484 6. Conclusion

485 In this paper, we used idealized simulations of lee waves over one-dimensional sinusoidal

486 bathymetry to demonstrate that for oceanic flow over supercritical height bathymetry, the lowest

487 layer of fluid becomes blocked and presents the over-topping flow with an effective bathymetry

488 defined by the lowest over-topping streamline (LOTS) that is subcritical in height and poly-

489 chromatic in wavelength. That the effective bathymetry reduces the apparent height of the hills is

490 well known and currently employed in parameterizations of lee wave drag in global ocean models.

491 However, both the development of evanescent undulations in the LOTS above the blocked layer

492 and the process of evanescent masking, in which the unseparated portion of the LOTS becomes

493 narrower than the lee wave wavelength, are novel results of nonhydrostatic lee wave processes in

494 this paper. Recognizing their deleterious effect on the wave drag in regions of supercritical ($J \geq 1$)

495 bathymetry may help explain the discrepancy between predictions using existing parameterizations

496 and observation of lee wave activity in the ocean discussed in Kunze and Lien (2019).

24

497 This study also offered an opportunity to observe the spin up of weakly nonlinear ($J = O(0.1)$) and

498 supercritical ($J \geq 1$) lee waves above periodic bathymetry. The excitation frequency, $T_{ex} = L_{hill}/U$,

499 emerged as the fundamental timescale of the lee wave for all simulations, regardless of hill height

500 or length, informing both the time required for spin up and the vertical location of the drag on the

501 background current. Furthermore, analysis of the horizontal momentum budget during spin up of

502 supercritical lee waves permitted a characterization of time-dependent local drag associated with

503 blocking.

504 The results in this paper identify four notable deficiencies in existing parameterizations of the

505 lee wave drag. 1) In supercritical regions ($J \geq J_c$), the simulations suggest that the steady-state

506 lee wave drag will be smaller than predictions with existing saturation parameterizations due to

507 the omission of nonhydrostatic effects of evanescent undulations and evanescent masking. 2) We

508 observe that the drag associated with blocking is constrained to the first excitation period when the

509 blocked layer forms, whereas predictions of the 'non-propagating' drag given by Garner (2005)

510 and used in Trossman et al. (2013, 2015, 2016) assume the blocking component of the drag is

511 a steady process that continually removes momentum from the flow. 3) On the other hand, in

512 regions with large but still subcritical height bathymetry ($J < J_c$), our parameterizations predict

513 larger lee wave drag because we identify the critical Froude number J_c and the effective Froude

514 number J_{aloft} separately, whereas existing saturation theory assumes them to be identical. 4)

515 Finally, our observations of upward propagating lee wave wave fronts in every simulation suggest

516 that all existing parameterizations need to reconsider confining the drag to within one lee wave

517 wavelength above the bathymetry.

518 There are inevitably some limitations in applying our conclusions uniformly throughout the

519 ocean. First, there is inherent uncertainty of approximately 30% in both the local height and length

520 of abyssal hills in the Goff and Arbic (2010) abyssal hill bathymetry product. On a regional scale,

25

521 this uncertainty is mitigated by the statistical homogeneity of the abyssal hills. Nevertheless, such

522 significant local uncertainty of abyssal hill length and width suggests that some of the details in

523 our process study, such as that of resonant responses for the $J = 1$ simulations, are probably not

524 worth including in a drag parameterization.

525 Second, the predicted drags F_{adj}, F_{Bell}, F_{eff}, F_{prop}, and F_{aloft} presented in Section 5 required

526 running the simulations to find the effective Froude numbers and the adjusted buoyancy frequencies

527 N_{adj}, meaning that these were not a priori parameterizations of the drag. With respect to the

528 effective Froude numbers, the aloft Froude number J_{aloft} gave the most accurate prediction of

529 the lee wave drag. Upon averaging across all supercritical simulations, we found the average

530 aloft Froude number of $\tilde{J}_{aloft} = 0.4 \pm 0.09$. The variability in this average stems primarily from

531 resonant responses rather than from nonhydrostatic effects. Hence our results support lee wave

532 drag parameterizations replacing $J_{NF} = 1.4$ with $J_{aloft} = 0.4$ above all 2-dimensional abyssal

533 hill bathymetry. Such a parameterization could also approximate the nonhydrostatic effect of

534 evanescent masking (Eq. 25) with a low-pass filter on the abyssal hill power spectrum to include

535 only hills for which $\epsilon < 0.5$. Using our results to parameterize N_{adj} is more difficult. As discussed

536 in Section 4, the decay of near-bottom buoyancy appears to depend on the progression of the valley

537 water over the top of the hill during the first excitation period of the simulation. This suggests that

538 N_{adj} is, at a minimum, a function of N, U, h_0, and k. Additionally, it involves mixing, which for

539 our simulations is a process driven by the elevated kinematic viscosity. In the real ocean, there

540 are likely further complications such as effects of the bottom boundary layer and hysteresis from

541 previous lee wave events. Hence the parameterization of N_{adj} requires further research.

542 Third, our study focused on single wavelength bathymetry, while the abyssal hills are better

543 described by a linear superposition of many wavelengths. As such, our study cannot account for

544 nonlinear interactions imposed by poly-chromatic nonlinear bathymetry. One hypothesis is that

26

the flow will adjust by filling in all valleys with stretches of evanescent undulations as observed above, whereafter the remaining unblocked peaks will likely represent a subset of the original bathymetric wave numbers. However, the hypothesis has not yet been tested with simulations. This is a significant limitation when attempting to employ the Goff and Arbic (2010) abyssal hill product.

Fourth, our study is of two-dimensional flow over one-dimensional bathymetry. In three-dimensional flow with two-dimensional bathymetry, fluid can travel around an obstacle rather than over it, and has been shown to reduce the saturation momentum flux by 40% (Nikurashin et al. 2014). However, abyssal hills are generally anisotropic, presenting the flow with a corrugation of ridges rather than a field of seamounts, which suggests that there may be little opportunity for flow around rather than over them.

Finally, our study ignores rotation. A primary consequence of rotation on lee waves is the lower bound on the bathymetric wavenumbers that produce propagating lee waves, based on the criterion $f < Uk$. As $Uk \to f$, the vertical wavenumber approaches infinity, whereupon the vertical group velocity and momentum flux vanish. Hence, our conclusions about the drag for an upward propagating lee wave require modification for longer wavelength hills in strongly rotational regions. A second rotational process that complicates our conclusions is that of lee wave frequency-band narrowing, resulting from the near-bottom decay of N during spin up of nonlinear lee waves (Eq. 14) such that the window of drag-producing bathymetry shrinks according to $f < Uk < N_{adj} < N$. If dramatic enough, or in regions of strong rotation, it could make all lee waves evanescent, snuffing out the lee wave drag (Kunze and Lien 2019). Finally, Nikurashin and Ferrari (2010a) demonstrate that in the Southern Ocean where rotation is strong, saturation-level velocities in the lee wave field are sufficient to excite inertial oscillations and elicit positive feedback that results in wave breaking within the first lee wave wavelength above the bathymetry and a local deposition of momentum.

27

Thus, in strongly rotational regions it may not be appropriate to deposit the momentum according to the vertical group velocity. However, even in this regime, the low-level breaking is a slowly-developing process. Nikurashin and Ferrari (2010a) observe the need for five or more days for inertial oscillations to grow over subcritical bathymetry even though the excitation period for their bathymetry was approximately just five hours. Therefore, there is ample time for the lee wave wavefront to propagate away from the bottom, depositing momentum as it travels before the development of instabilities related to the inertial oscillations.

Despite the many simplifications, this paper demonstrates the remarkable applicability of linear lee wave theory to real ocean-scale flow. During spin up, F_{lin} (Eq. 3) offered a good estimate for the peak value of the form drag in all simulations, and was especially accurate when $\epsilon < 0.5$, where evanescent masking is less pronounced. After spin up, the observed quasi-steady wave drag was best predicted with the same linear theory but with the hill height replaced with the maximum vertical extent of a streamline aloft F_{aloft} (Eq. 24). The second best prediction came from inserting the power spectrum of the effective bathymetry into the spectral form of linear lee wave drag (Bell 1975b). These should not be foregone conclusions, since linear theory is strictly valid only for $J \ll 1$, whereas the effective bathymetries in our simulations presented effective lee wave Froude numbers of $J_{aloft} \approx 0.4$. Granted, achieving such accurate predictions required simulating the full flow to compute the adjusted bottom buoyancy frequency and the effective bathymetry. Still, our results demonstrate that even in the supercritical regime, linear theory can explain the lee wave drag. In this sense, they represent a qualified triumph of linear lee wave theory.

Data availability statement. Matlab data files for each simulation as well as Matlab scripts to generate all figures used in this paper are provided in the Stanford Digital Repository (https://purl.stanford.edu/jy494jz4178).

LIST OF TABLES

34

699 TABLE 1. Table of coefficient of determination R^2 values for all steady-state parameterizations considered in

700 Section 5 using N_{adj} (Eq. 14), as well as the values obtained by using N instead. Since F_{aloft} only uses N, the

701 two values for F_{aloft} are identical.

	N_{adj}	N
F_{lin}	-53.1	-83.4
F_{Bell}	0.91	0.305
F_{eff}	-0.296	-1.55
F_{prop}	0.733	0.146
F_{aloft}	0.956	0.956

35

LIST OF FIGURES

36

37

760   Fig. 1. A lee wave generated over sinusoidal bathymetry of length L_{hill} and height h_0 resulting from uniform

761   background flow with horizontal velocity U and buoyancy frequency $N^2 = \frac{g}{\rho_0} \frac{\partial \overline{\rho}}{\partial z}$, where g is the gravitational

762   acceleration, $\overline{\rho}$ is the background density of the fluid, and ρ_0 is the reference density. The color contours and

763   white lines are the instantaneous vertical velocity and simulated streamlines at time $t = T_{ex} = L_{hill}/U$, taken from

764   one of the simulations reported in this paper ($J = 1.2$ and $\epsilon = 0.16$). The characteristic wavelength between lines

765   of constant phase is $\lambda_{lee} = 2\pi U/N$, as sketched with dotted black lines. The colormap is 'deep' from Thyng

766   et al. (2016).

38
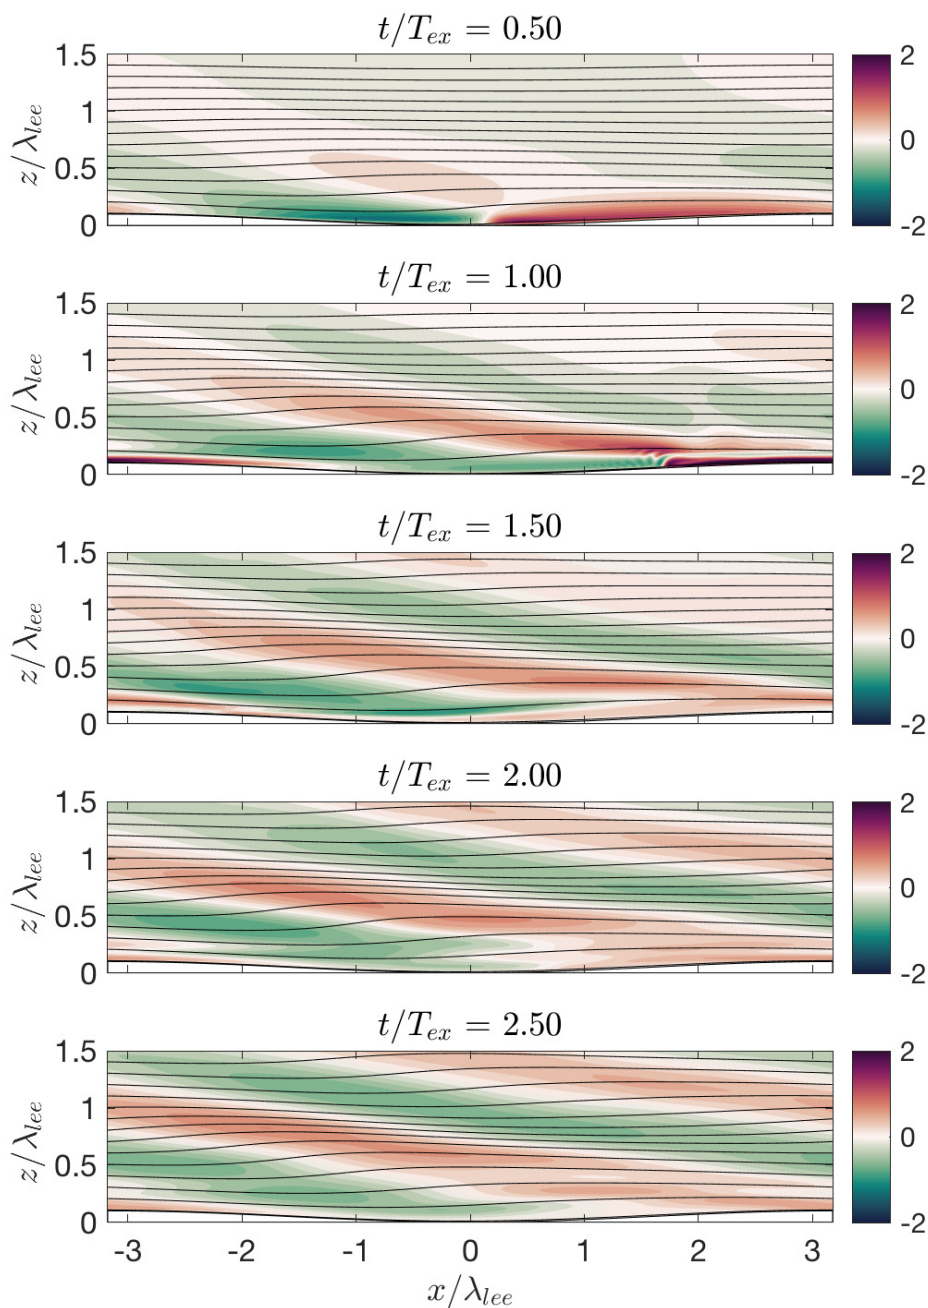

767   FIG. 2. Nondimensional vorticity ($\omega^* = \omega/(JN)$) and streamlines at half T_{ex} intervals for the simulation with

768    $J = 0.6$ and $\epsilon = 0.16$ ($h_0 = 60$ m, $L_{hill} = 4$ km). The colormap is 'curl' from Thyng et al. (2016).
39

FIG. 3. Horizontally-averaged local buoyancy frequency $\langle N \rangle$ (Eq. 13) as a function of height above the valley bottom for the simulation shown in Fig. 2. Each line corresponds to a moment in the simulation, as indicated in the legend. The horizontal dashed line is at a height $z = h_0 + U/N$ ($z/\lambda_{lee} = (J+1)/2\pi$) above the valley bottom.

40
FIG. 4. Computed form drag (dot-dashed line, Eq. 9) and vertical momentum flux through a plane 15 m above the crest of the hill (solid line, Eq. 10) as a function of time for the simulation in Fig. 2. Also shown are the predictions of linear theory using the background buoyancy frequency (dotted line, Eq. 3) and the adjusted buoyancy frequency (dashed line, Eq. 15).

41
FIG. 5. Horizontally averaged vertical momentum flux as a function of height above the valley bottom for the simulation in Fig. 2 (Eq. 10). Each line corresponds to a moment in the simulation, as indicated in the legend. The horizontal dashed line is at the height $h_0 + 15$ m above the valley bottom.

42
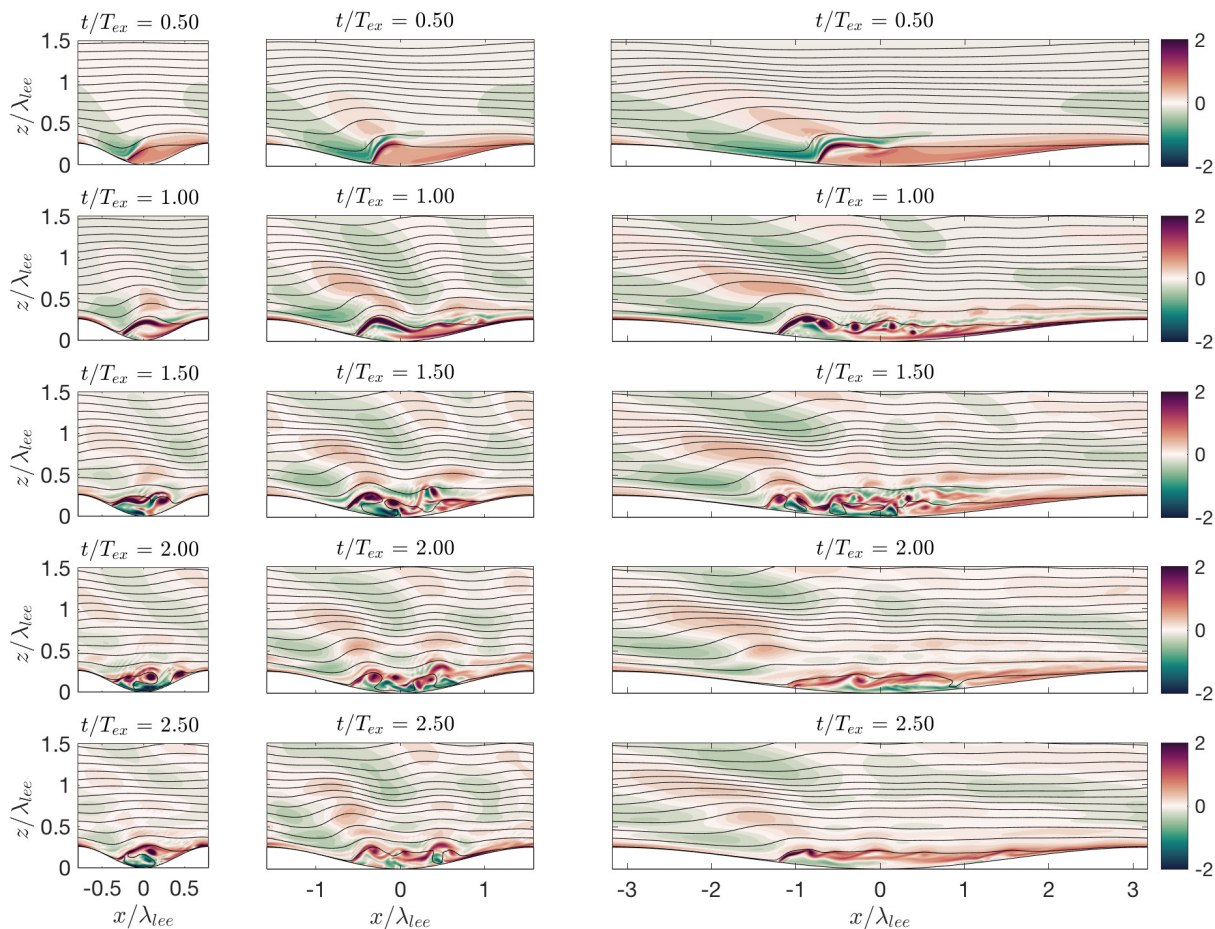

FIG. 6. Snapshots in time of nondimensional vorticity ($\omega^* = \omega/(JN)$) and streamlines at half T_{ex} intervals for the simulations with $J = 1.6$ and $\epsilon = [0.63, 0.32, 0.16]$ ($h_0 = 160m$, $L_{hill} = [1,2,4]$ km). All panels employ real aspect ratios and have their axes nondimensionalized by the lee wave wavelength, $\lambda_{lee} = 2\pi U/N$.

43
₇₈₂ Fɪɢ. 7. Comparison of vertical momentum flux through a horizontal plane 15 m above the crest of the hill,

₇₈₃ F_{flux} (Eq. 10), to the form drag, F_{form} (Eq. 9). The values are nondimensionalized by the saturation drag,

₇₈₄ $F_{sat} = \rho_0 U^3 N^{-1}$. Cross hatch pattern indicates local deposition of momentum during spin up (Eq. 12).

44
₇₈₅ Fɪɢ. 8. Maximum computed momentum flux (top), form drag (middle), and predicted drag from linear theory

₇₈₆ for all simulations. The values are nondimensionalized by the saturation drag, $F_{sat} = \rho_0 U^3 N^{-1}$.

45
FIG. 9. Snapshots in time of LOTS (solid blue lines) at half T_{ex} intervals for the simulation with $J = 1.6$ and $\epsilon = [0.63, 0.32, 0.16]$ ($h_0 = 160$ m, $L_{hill} = [1,2,4]$ km). Real bathymetry is shown as dashed black lines.

46
FIG. 10. Time-averaged vertical momentum flux $\overline{F}_{SUN}$ (Eq. 17) normalized by $F_{sat} = \rho_0 U^3 N^{-1}$ (Eq. 5, top), F_{lin} (Eq. 3, middle), and F_{adj} (Eq. 15, bottom) as a function of J for all simulations. Each simulation is represented by a circle. The size of the circle indicates the relative length of the hill, while filled circles indicate blocking.

47
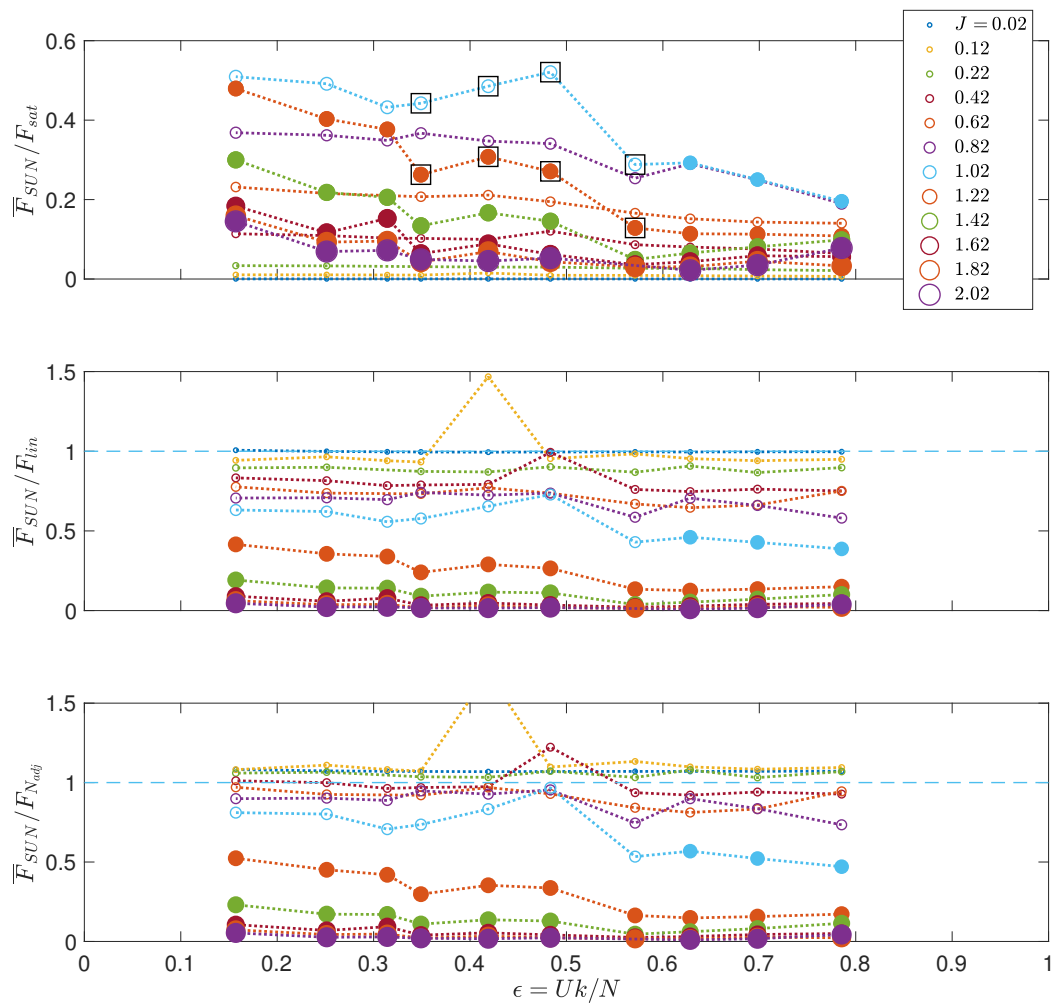

FIG. 11. As in Fig. 10 but as a function of ϵ for all simulations. The simulations highlighted by squares in the top panel display non-monotonic behavior due to resonance.

48
795 FIG. 12. Comparison of time-averaged vertical momentum flux $\overline{F}_{SUN}$ (Eq. 17) to the prediction from buoyancy-
796 adjusted linear theory F_{adj} (Eq. 15). For each simulation, J and ϵ are indicated by, respectively, the color and
797 the size of the data point. The coefficient of determination is $R^2 = -53.1$.

49
FIG. 13. Time-averaged LOTS (blue solid line) and streamlines starting at $z = h_0 + 0.5 \; \lambda_{lee}$ (red dotted lines) corresponding to the simulations shown in Fig. 6. The aspect ratio is 2:1 to accentuate vertical perturbations.
50

FIG. 14. Sketch of the effective bathymetry (LOTS) and its characteristic height and length scales from the

simulation with $J = 1.6$ and $\epsilon = 0.16$.

51
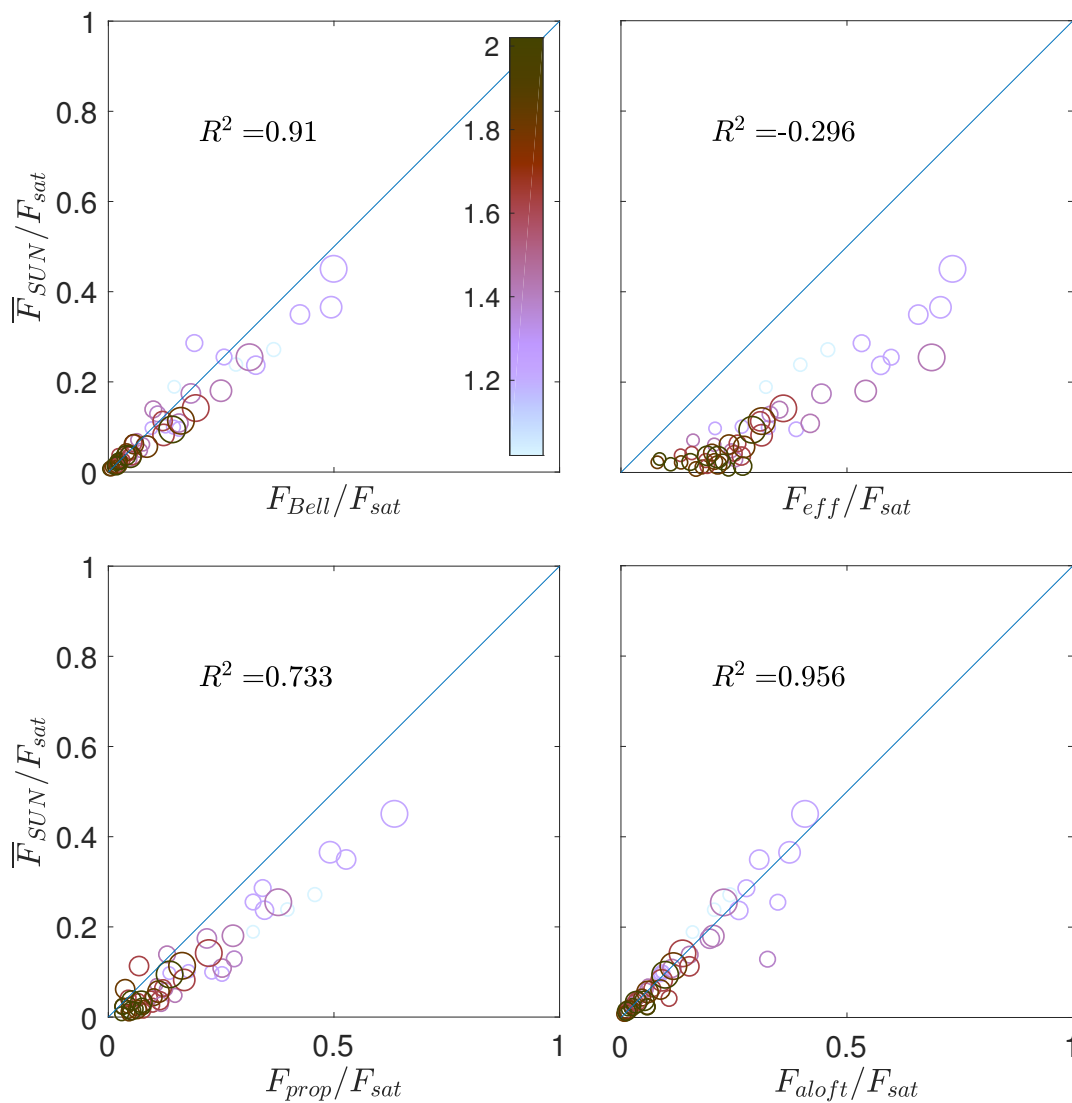

802   Fɪɢ. 15. As in Fig. 12, but now comparing to F_{Bell} (top left), F_{eff} (Eq. 21, top right), F_{prop} (Eq. 22, lower

803   left), and F_{aloft} (Eq. 24, lower right). Only the simulations that exhibit blocking are displayed. The coefficients

804   of determination (Eq. 18) are indicated in each panel.
FIG. 16. Parameterized and time-averaged drags for all simulations. The black line plotted with $\overline{F}_{flux}$ (top left panel) shows the drag-free boundary predicted by evanescent masking (Eq. 25).

53
